
Listing 2: Three constraint hypotheses, as expression edges on the same components. Each `bind` states a relationship the analyst believes and the fit must then honour; none of them is expressible to `curve_fit`. The last ties a parameter of one spectrum to a parameter of another, which is what makes scenario D a single joint fit rather than two fits compared afterwards.

```
# B: the 2p3/2:2p1/2 edge-jump degeneracy, 2:1
graph = compose(nodes).bind("step_l3.amplitude / 2", to="step_l2.amplitude")

# C: the L2 white line sits one spin-orbit splitting above the L3 white line,
#     the splitting being the fitted separation of the two continuum steps
graph = graph.bind("p1.center + step_l2.center - step_l3.center", to="p7.center")

# D: ...and that splitting is the SAME atom in both complexes, so the d6 white
#     line is displaced by the splitting the d5 spectrum determines
graph = graph.bind("b_p1.center + a_step_l2.center - a_step_l3.center",
                  to="b_p8.center")
```
